Structural engineers are increasingly finding themselves assessing existing structures rather than designing new ones. These need to be checked because loads have changed or the materials have deteriorated, or simply because the owner (or an insurance company) wants reassurance that the structure is adequate. Many of these structures are failing the checks, which results in work for the engineer but expense for the client and a feeling amongst the general public that we are surrounded by bridges and buildings that are inadequate. But is this really the case? Very few structures actually collapse because a slightly increased load overcomes a slightly reduced load capacity caused by corrosion. Gross errors do happen – a 20t truck driven over a bridge with a 2t weight limit is not something the engineer can be blamed for, but corrosion of critical structural elements, such as prestressing tendons, is something for which engineers should check. The problem to which this paper is addressed is the structure which has apparently been giving engineers concern. The relationships are considered between elastic theory and plastic theory, design methods and analysis methods, and the upper and lower bound theorems. These raise various conflicts for engineers that can have important consequences.

Most engineers have been taught the fundamentals of plasticity theory. They know how to perform a plastic collapse analysis of a frame, or carry out a yield line analysis of a slab. They know that these give an upper bound on the collapse load and are thus ‘unsafe’. They are aware that there is also a lower bound theorem, but circumstantial evidence shows that most engineers cannot quote it and do not believe that they use it. This is paradoxical, since they rely on it every time they design a structure.

Elastic and plastic methods of design give different answers when the structure is indeterminate, since the stress distribution is not defined purely by equilibrium. Beams and frames have limited degrees of indeterminacy, but plates and slabs are infinitely indeterminate so there the differences between the two approaches can be expected to be most apparent. Bridge decks are such structures, and all bridges are currently being reassessed.

The rise of computer methods of analysis has allowed ‘exact’ solutions to be obtained for structures that would have been far too difficult to analyse only a few years ago. It is relatively easy now to carry out a finite element analysis of a deck slab and to produce a plot of moments, stresses and deflections. Tables and plots can be produced in great detail which give apparent assurance that the results are accurate. The accuracy of the solution relies on knowledge of the elastic stiffnesses of the structure, and their distribution, which can be critically important when the structure is of reinforced concrete which is partially cracked or when the materials creep differentially. Slight variations of the support conditions can have a dramatic influence on the distribution of moments. An elastic analysis is thus making a sweeping set of assumptions that may not be justified.

To illustrate these various aspects, consider a hypothetical reinforced concrete slab structure. It will be assumed that the structure was designed 30 years ago using the relevant methods of the day, and is now being assessed using current techniques. No safety factors will be taken into account, since they cloud the issue, so applied loads and capacities can be compared on a one-to-one basis. What would today’s engineers recommend to the owners of that structure?

The structure

The structure is a rectangular slab made from reinforced concrete, simply supported on all sides. It has an aspect ratio ($\mu$) of 2, with the shorter sides of length $a$. It was designed to carry a uniformly distributed load of intensity $q$. The geometry is shown in Fig 1, which matches the notation used in Timoshenko and other papers to which reference will be made. It is assumed that the slab was designed with orthogonal reinforcement. Steel in the bottom of the slab, parallel to the x-axis, resists the sagging moment $M_a$. Moments such as $M_a$ are expressed as moments per unit width and in the plots will be non-dimensionalised by dividing by $qa^2$. It is assumed that the structure, as with most reinforced concrete slabs, is sufficiently under-reinforced, in accordance with relevant codes, so that full ductility is assured.

The design

It is assumed that the structure was designed in 1970 by a bright young engineer fresh out of college. Engineers would not have had access to calculators, let alone computers, so complex calculations for a simple structure such as this would not have been justified. The designer would be assumed to know about the methods for the elastic analysis of such slabs, such as the Fourier techniques used in the Navier analysis, but would not have had the time to sum by hand the infinite series that the solution required. But he would also have known about the Hillerborg strip method of design which would have been quite appealing. According to this theory, which is still taught today and would still be regarded as a perfectly reasonable method of design, the slab is imagined as a series of intersecting orthogonal strips. By apportioning the load between the two sets of strips, and designing suitable reinforcement on the assumption that the strips are simply supported beams, the designer has reduced an infinitely indeterminate plate to two statically determinate beams. The only question that the designer has to decide is the proportion of load to put onto each of the two strips. He chooses to put a proportion of the load $aq_1$ onto the short strips, and the rest $(1 – aq_1)$ onto the longer strips. He knows that whatever value of $aq_1$ he chooses will satisfy the lower bound theorem, which states:

If any stress distribution throughout the structure can be found which is everywhere in equilibrium internally and balances certain external loads and at the same time does not violate the yield condition, those loads will be carried safely by the structure.

The important word in this theorem is ‘any’. Whatever value of $aq_1$ he picks, the solution will still be in equilibrium with the applied loads, so the moments obtained can be used as a basis for designing the reinforcement.

However, the engineer believes that it is a ‘good thing’ to make his value of $aq$ ‘reasonable’. He achieves this by saying that he will choose $aq$ such that the deflections in the two strips that intersect at the centre of the slab are equal (Fig 2). This is likely to mean that the two strips will deflect together, which will in turn mean that there will be no premature cracking.

A simple elastic calculation for a simply supported beam shows that this deflection criterion gives...
\[ \alpha = \frac{\mu^2}{1 + \mu^2} \]

so that when \( \mu = 2.0 \), \( \alpha = 0.941 \).

The engineer can then design the reinforcement in the two directions, and to be economic, he curtails the reinforcement as soon as possible, so that the resistance moment follows very closely the applied moment. He has thus satisfied the second requirement of the lower bound theorem – that the applied moment nowhere exceeds the moment of resistance.

The designer knows that the moment field that he is designing for is not ‘correct’, but he also knows that if the steel in one direction is overloaded, either that steel will yield or the concrete will crack more extensively, which will shed any additional load from the stiffer strips onto the less stiff strips. The structure is safe.

The moment capacity fields provided to the slab in this way are shown in Figs 3 and 4.

History of the slab
The scenario continues by assuming that the structure was built to the design, using satisfactory materials and workmanship, and that it has suffered no exceptional events during its life to date. The owner now wishes to have the structure checked, so another engineer is approached to carry out an assessment. In the meantime, the original designers have ceased trading and the original calculations have been lost, although a set of as-built drawings has survived in the client’s files. A check of the structure shows no signs of corrosion. The owner expects the check to be a formality.

The assessment
The engineer who is checking the structure is also a recent college graduate. She is adept at using computer analysis packages, so she carries out a finite element analysis. The slab is of uniform thickness and she has no knowledge of its state of cracking, so she takes a uniform stiffness everywhere. She takes Poisson’s ratio (\( v \)) for concrete as 0.2 and she ends up with results for three different moments, \( M_x, M_y, \) and \( M_{xy} \), as shown in Figs 5, 6 and 7. (The figures have been derived from a Navier solution – they are what she would get if she did a finite element analysis correctly.)

She uses the original drawings to determine the existing moment capacities of the slab, which match those found by the original designer. The applied \( M_x \) moments are considerably less than the apparent moment capacity, but, disturbingly, the \( M_y \) moments seem lower than the applied moments, and the maximum is not at the centre. There are also the \( M_{xy} \) moments to deal with. The finite element package can cope with this, however, since it has the Wood-Armer equations built-in, so she can also determine the amount of steel that the designer ought to have used.

Wood-Armer equations
The Wood-Armer results for the bottom steel are shown in Figs 8 and 9, which should be compared with Figs 3 and 4. The \( M_x \) capacity required is still less than that provided at the centre, but not at the corners; the \( M_y \) capacity is insufficient almost everywhere.
...and the Wood-Armer equations also show that top steel is clearly insufficient, and by a large margin. To make matters only in two small regions – elsewhere the moment capacity is applied moments. Values >1 are satisfactory, but this occurs external load so that the bottom steel is sufficient to carry the of the, as yet unknown, moments of resistance provided by the

Note that the capacity is always greater than the applied moment; the equations also minimise the steel required in two specified directions (here 0° and 90°).

Various special cases were identified to allow for situations where these equations required moments of the wrong sign.

Denton’s equations
Denton recognised that structures were failing assessments because of the optimisation criterion imposed by Wood and Armer. It is of no concern to a checker that the reinforcement is not optimal. The assessor does not have to choose the reinforcement, she only has to check whether the applied moment is less than the resistance moment for all orientations. Denton published these equations in a form that determines the limiting factor γ by which the applied moments have to be multiplied so that they lie below the resistance moment for all orientations.

If γ is everywhere greater than 1 the structure is inadequate – if not it is, at least locally, overstressed.

So the checker applies these equations to find γ everywhere, and plots the results as shown in Fig 11, which is in a similar format to Fig 11. The results are better, but still show that the slab is unsatisfactory in many areas, particularly in the corners of the slab, where Mx is high. γ factors as low as about 0.20 are present, and even in the middle of the slab, where Mx is zero, γ is as low as 0.63.

These equations tell us nothing about the top steel, none of which was provided by the designer.

The checker thus concludes that the slab is inadequate, and recommends significant refurbishment, perhaps using glued-on carbon fibre strips.
The client

The client is dissatisfied. He is informed that the structure he has been using for 30 years, without any problems and without any indication of damage, has a strength that is only a fraction of what it was designed for. He does not believe that a structure so weak would have survived without problems especially since, without admitting it to the engineers, he suspects he has been overloading it anyway. So he requests a second opinion.

Yield line analysis

As a check on the assessment, a yield line analysis is carried out. This had not been done before since the checker knows that it is an upper bound, and thus ‘unsafe’. The second checker uses a simple yield line mechanism (Fig 14), with a single pattern parameter, which gives a load factor of 1.0 that is independent of the value of the pattern parameter. A more complex pattern (Fig 15), with a hogging hinge in the corner, which ordinarily gives a lower collapse load, in this case gives a higher one. Despite extensive searching, no mechanism can be found with a collapse load factor less than one. The structure is declared safe and the client is happy, but the checking engineers feel they have lost a fruitful contract to repair a deficient structure.

Discussion

Some elements of this scenario would be familiar to most engineers working today. The example is hypothetical, and to a certain extent unrealistic. No additional safety factors have been applied which would have provided more reinforcement than was actually required. Only a single load case was considered and the reinforcement was curtailed more than would have taken place in practice. No code rules for minimum steel were applied, which would certainly have led to a slab that was stronger at its edges than is suggested here, and no options for varying the proportion of load carried in the edge strips and mid-span strips were applied. These factors would have masked the basic problem rather than being a solution for it.

External observers, blessed with perfect knowledge and hindsight, can comment on the roles of the various protagonists. Can they be criticised or should modern procedures be modified?

The original designer applied the logic of Hillborg’s method correctly. He may be accused of being a little simplistic in choosing a single distribution factor over the whole slab, but his attempt to equate the deflections of the intersecting strips at the centre the slab is reasonable.

Was the first checker at fault? Her reliance on computer analysis would be very typical of the procedures today. Finite element programs are cheap and easy to use – she probably spent less time setting up her analysis than the author of this paper did in writing the Fourier series solution. Did she make a mistake in using the Wood-Armer equations? Yes, but she corrected it by using Denton’s equations instead. Where she was at fault was her reliance on what the plasticity community has come to call ‘Navier’s straitjacket’. This is a rigid belief that the solution produced by an elastic analysis is the true answer. The finite element package she used was linear, and had a uniform stiffness in all directions. She knew that the structure would crack, which would shed loads from one direction to another, but it is very difficult to follow the true load-deflection path since it depends so much on the history of the slab, on the yield strength of the reinforcement and its bond characteristics, and on the tensile strength of the concrete, most of which are unknown and unknowable. It would be possible to carry out a non-linear finite element analysis, which would supposedly allow these effects to be taken into account, but a large number of assumptions would be required, it would take a very long time to set up and run, and the results would be unlikely to be any more correct than the linear analysis.

Any elastic solution, such as the finite element or the Fourier series, gives a set of moments that is in equilibrium with the applied loads. Thus, even if it is not the correct solution, a linear elastic analysis can be used as the basis of a lower bound solution, which is ideal for design. That is the reason for the assertion at the beginning of the paper that most designers rely on the lower bound theorem every time they design a structure. They only need to ensure that they have an equilibrium set of moments and the capacity to resist them. Knowledge of the ‘true’ stress-state of the structure is a chimera.

Could the checker reasonably have done anything else? She could have presumed that a lower bound method was used for design, but it would be difficult for her to check; there are an infinity of different ways in which the distribution factor for the loads could have been chosen. What is simple for the designer is very complex for the assessor. Knowing the reinforcement but not knowing the details of the design procedure, she could have broken the slab down into strips parallel to the reinforcement. She could have determined the loads that would just cause the moment capacity to be reached everywhere in one set of strips, and then checked whether the rest of the loads could be carried by the other set of strips. In a simple case like the one being considered here, such an approach is feasible, but in more complex cases it would be very difficult.

Is it surprising that the upper bound method gave a load factor of 1? The original design provided just sufficient reinforcement to cope with the applied loads. Any increase in load would have caused the strips to yield all along their length in both directions. So a simple yield line mechanism, which allows all the applied loads to do positive work, and the whole of the slab to contribute to its resistance, is bound to give a load factor of 1.0. The more extensive mechanisms, where there is a corner of the slab in which the load does no work, are bound to give higher collapse loads. If a slab has uniform moment of resistance, corner fans can reduce the collapse load by about 10%, but here the yield lines in the corner do very little work since the moment capacity is so low.

It is also worth pointing out that any method of design that apportioned the load according to a set of rules (such as code rules for central and edge strips) would have fallen foul of the assessment procedures, because they would similarly have relied on a lower bound plasticity approach to design. So the paradox...
remains that a structure could even be designed one day, and fail its assessment the next, without ever having been used.

Caveats
The ideas in this paper are generally applicable, but some words of caution are necessary. If the structure is going to change its method of carrying loads from the elastic distribution to the fully-plastic one as it cracks or deforms it must have enough ductility for this to occur. If it does not have enough ductility the structure will fail when some component or element fails by overstressing. This does not make the finite element result correct – the designer may well still not know the support conditions or the stiffnesses properly – but it does mean that plasticity cannot be relied on.

In concrete structures, the most frequent reason for not being ductile is if the structure fails in shear. If the moments are being redistributed, equilibrium requires also that the shears are redistributed, so the structure must be capable of carrying not only the shear in the original elastic state, but also any state it passes through en route to the final solution.

For steel structures, stability must be considered. If the structure, or an element within it, fails by buckling, then redistribution cannot occur. This can happen even in highly redundant steel structures, such as double-layer grids. These structures are so indeterminate, and their initial stress-state so dependent on the way they are built, that they rarely reach their nominal capacity due to premature buckling in compression members whose initial stress state is not known accurately. A finite element analysis is of no help because the designer does not know what state of self-stress to build in (even if the f.e. package allows such a thing).

The paper does not address other geometrical effects, such as membrane action or P-δ effects. These often enhance the strength of concrete structures but degrade the capacity of steel structures.

Steel structures are also sensitive to fatigue problems. These stresses are dependent on the range of elastic stresses, and an elastic finite element analysis can be relevant here, since the total load is not being considered, only a small varying component of it.

Conclusions
What lessons can be learnt as a profession when trying to make the most of our existing structures?

- Remember the underlying structural principles, especially of the lower-bound theorem.
- Remember that linear elastic solutions and lower bound techniques like Hillerborg, are primarily useful for design.
- Make structures deformable, so that the redistributions inherent in plasticity theory can take place.
- If a structure is to fail it must have a collapse mechanism, whose collapse load can be computed by an upper bound analysis.
- A computer analysis is only as accurate as the assumptions that underlie it. If the stiffness of a support is unknown, or the elastic modulus of the concrete is unknown, the stresses that depend on it will be wrong. Neatly printed garbage is still garbage.
